Eight out of 30 consecutive patients with AIDS and cryptococcal meningocerebralitis (26.7%) presented cutaneous involvement, in the form of papulo-nodular lesions in 3 patients, molluscum contagiosum-like lesions in 3 patients, and pustular-ulcerative lesions in 2 patients. Skin localization represented an untoward prognostic sign, and in 3 out of 8 patients the lesions were diagnosed 2 to 6 weeks before the onset of systemic and neurologic signs and symptoms of the disease. A systematical examination of all suspected cutaneous lesions in subjects with advanced HIV disease may lead to an earlier diagnosis and treatment of disseminated cryptococcosis. Key words: HIV/AIDS; clinical picture; prognosis.

Skin diseases and cutaneous localization of systemic disorders are important clinical features in patients with HIV infection, and in some cases they may represent early diagnostic clues or useful prognostic markers of disease progression (1).

Cutaneous manifestations of systemic fungal infections may show a polymorphic clinical picture and a variable relationship with the disease course, when compared with those recognized in compromised patients without HIV disease (1–3).

In order to assess the incidence, morphologic features, and clinical significance of the cutaneous localization of Cryptococcus neoformans infection in patients with AIDS, we systematically evaluated all suspected skin lesions observed in severely immunocompromised HIV-infected patients for possible fungal involvement, both in subjects with and without an established diagnosis of cryptococcosis.

RESULTS

Eight out of 30 consecutive subjects developing extrapulmonary cryptococcosis (26.7%) (all males, aged 26 to 50 years; 6 i.v. drug abusers, one homosexual, and one heterosexual) presented cutaneous C. neoformans infection. Papulo-nodular lesions were observed in 3 patients, molluscum contagiosum-like lesions in 3 patients (Fig. 1), and pustular-ulcerative lesions in the remaining 2 patients (Table 1). They were localized to the face and neck in 7 cases, chest and back in 4 cases, and upper or lower extremities in 3 cases, in number ranging from 2 to over 100. Large amounts of fungal organisms were easily disclosed by histopathological studies, which always showed a massive cryptococcal infiltration of both epidermis and dermis, associated with a poor to moderate inflammatory reaction containing scattered multinucleate giant cells and histiocytes (Fig. 2).

All subjects with skin localization suffered from (or

PATIENTS AND METHODS

Clinical and microbiological records of our series of 390 patients with AIDS were retrospectively reviewed, in order to identify all subjects suffering from extrapulmonary cryptococcosis.

The cutaneous localization of this opportunistic mycosis was diagnosed by considering the clinical picture and histopathological and culture studies of skin biopsy specimens or clinical samples obtained by cutaneous scarification, performed by standard techniques.

The occurrence of fungal skin lesions was related to several clinical, laboratory and prognostic variables of disease evolution.

therapy, while only 2 subjects obtained clinical remission associated with the cure of fungal skin lesions.

DISCUSSION

Cutaneous localization is known to involve less than 10% of AIDS patients suffering from extrapulmonary cryptococcosis, when large series of HIV-infected subjects with this fungal complication are reviewed, and is usually considered as a sign of disseminated infection appearing only in the late stages of the disease course (2, 4–6), even if primary cutaneous cryptococcosis has occasionally been observed in this patient group (7). Morphologic features of cryptococcal skin lesions have been described mostly as single case reports (2, 8–11): their broad clinical spectrum includes polymorphic aspects, often leading to a problematic differential diagnosis, since they can resemble other skin diseases or other cutaneous manifestations of systemic AIDS-related disorders (2–4, 8–11). Abscesses, cellulitis, nodules, papules, pustules, granulomas, ulcers and patches may be observed, as single or more frequently multiple skin lesions, with occasional involvement of oral mucosa; in a considerable number of cases, skin localization can mimic other disorders commonly found in AIDS patients, such as Kaposi's sarcoma, molluscum contagiosum, ulcerative herpes, acne, pyoderma gangrenosum, or purpura (2–4, 8–11). In very rare cases, mostly during the pre-AIDS era, skin involvement has been reported to precede the appearance of signs and symptoms of disseminated disease and to represent the sole clue to diagnosis (2, 12).

In our series, cutaneous localization of C. neoformans infection showed a remarkably increased incidence when compared with literature series (4–6, 10), and in 3 out of 8 cases it occurred even 2 to 6 weeks before the first appearance of neurologic and systemic signs and symptoms of disease, thus representing an early clue of initial disseminated cryptococcosis.

In conclusion, our experience suggests that a careful clinical, microscopic, cultural, and histopathological examination of all suspected skin lesions in patients with advanced HIV disease, even without evident signs and symptoms suggestive of systemic complications, may lead to an earlier recognition of extrapulmonary cryptococcosis, thus allowing a timely specific treatment of this potentially fatal opportunistic disease.
