Febrile ulceronecrotic Mucha-Habermann disease (FUMHD) is a rare fulminant variant of pityriasis lichenoides et varioliformis acuta (PLEVA) that is characterized by a large ulceronecrotic appearance with high fever and a variety of systemic symptoms. We report here a case of FUMHD in a 17-year-old male Chinese patient who was treated successfully with a combination therapy of methotrexate, methylprednisolone, and intravenous immunoglobulin. In addition, a literature review was conducted to summarize the key characteristics of paediatric FUMHD cases.

Key words: febrile ulceronecrotic Mucha-Habermann disease; FUMHD; pityriasis lichenoides et varioliformis acuta; PLEVA.

SIGNIFICANCE

A 17-year-old male patient was diagnosed with febrile ulceronecrotic Mucha-Habermann disease (FUMHD), a rare and severe form of pityriasis lichenoides et varioliformis acuta (PLEVA). The patient was treated with a combination of methotrexate, methylprednisolone, and intravenous immunoglobulin, and a favourable outcome was achieved. A literature review of paediatric cases of FUMHD was performed to summarize the characteristics of this condition in the paediatric population and to emphasize the importance of prompt recognition and appropriate treatment.

Pityriasis lichenoides et varioliformis acuta (PLEVA), or Mucha-Habermann disease, is the acute form of pityriasis lichenoides characterized by erythematous, scaly papules often accompanied by haemorrhagic and papulonecrotic lesions. First described by Degos in 1966 (1), febrile ulceronecrotic Mucha-Habermann disease (FUMHD), also known as PLEVA fulminans, is considered a rare and severe variant of PLEVA. Patients with FUMHD usually present with typical PLEVA lesions, but progress rapidly into a large ulceronecrotic appearance, accompanied by high fever and a variety of systemic symptoms. FUMHD can be life-threatening.

This paper presents a destructive case of FUMHD in a 17-year-old male, which was treated successfully with a combination therapy of methotrexate (MTX), methylprednisolone and intravenous immunoglobulin (IVIG). FUMHD can occur in individuals of almost any age. To the best of our knowledge, over 100 cases of FUMHD have been published in the literature, with the youngest patient being a 9-month-old boy and the oldest being an 82-year-old woman (2, 3). A previous systemic review demonstrated distinct outcomes between paediatric and adult populations with FUMHD. Adults had a significantly higher mortality rate than children, and mortality rates increased with the age of the patients (4). However, an up-to-date comprehensive evaluation of FUMHD in the paediatric population is lacking. To gain a better understanding of the disease characteristics in this population, a literature review was performed of previously reported paediatric FUMHD cases.

CASE REPORT

A 17-year-old Chinese male was admitted to our department with a 12-day history of an abrupt onset of rapidly spreading erythematous macules, papules and vesicles that gradually developed into central ulceronecrotic and crusting lesions. The eruption initially appeared on the abdomen, with subsequent extension to the chest, back and extremities. The patient reported mild pain and itching at the affected sites and had symptoms of general malaise. He was diagnosed with erythema multiforme at the local hospital and treated with methylprednisolone and compound glycyrrhizin injection. Despite the treatments, the patient's eruption consecutively disseminated, and he developed fever 1 day prior to admission, with a maximum body temperature of 38.7°C. There was no personal or family history of dermatological diseases. He denied receiving any medications or having an infection before the eruption. He also reported no recent vaccination history.

Physical examination revealed abundant erythematous macules, papules, papulovesicles and papulopustules with central haemorrhagic necrosis. Some of the haemorrhagic necrotic centres were covered with thick crusts, while others had formed erosions and ulcers (**Fig. 1**). Although different evolutionary stages were present at the same time, older lesions were distributed on the trunk, whereas more fresh lesions developed on the extremities, indicating a progression of the lesions distally. Enlarged lymph nodes were palpated in both armpits.

The laboratory findings at admission showed elevated levels of inflammatory markers, including an erythrocyte sedimentation rate (ESR) of 21 mm/h, a C-reactive protein (CRP) of 47 mg/L, and leukocytosis (10.6×10^9/L) with 76.8% neutrophils. Repeated blood cultures were sterile. The skin swab cultures, however, tested positive for methicillin-resistant *Staphylococcus*

aureus (MRSA). Other significant laboratory parameters included hypoalbuminemia (33.4 g/L) and occult stool (+). Screening tests for infectious diseases (human immunodeficiency virus, syphilis, hepatitis viruses, Epstein–Barr virus (EBV) and parvovirus B19) and autoimmunity were negative. Gastroscopy showed superficial atrophic gastritis and gastric ulcers. Skin biopsy from the abdomen was performed on the first day of admission, and histology revealed epidermal parakeratosis, focal epidermal oedema, liquefactive degeneration of basal cells, and perivascular lymphocyte infiltration (**Fig. 2**). The immunofluorescence test was negative.

PLEVA was considered the initial diagnosis, and the patient was treated with intravenous methylprednisolone 60 mg daily and piperacillin sodium and tazobactam sodium. The diagnosis was replaced by FUMHD based on rapid progression, the development of ulceronecrotic lesions and histological examination. Antibiotics were subsequently adjusted to vancomycin and levofloxacin according to skin swab culture of MRSA and the patient's treatment response. A course of ribavirin for 5 days was also added to treat potential viral infection. Ibuprofen was prescribed for fever. Wound care was provided with topical mupirocin and wet dressing. Despite prompt treatment, the patient's condition deteriorated, new lesions continued to develop (**Fig. 3**), and his temperature suddenly jumped to 40.2°C on hospital day 25. His inflammatory markers, such as CRP and procalcitonin (PCT), also peaked. Thus, we administered methylprednisolone pulse therapy (300 mg daily on the first day, 200 mg daily on the second day and 100 mg on the third day), together with 2 doses of methotrexate (15 mg weekly) and IVIG for 7 days. At the same time, the antibiotics were converted to imipenem/cilastatin and minocycline. Major treatments and body temperature are shown in **Fig. 4**. After the initiation of methylprednisolone pulse therapy, methotrexate and IVIG, the patient's cutaneous condition stabilized. Although the patient's skin eruption has demonstrated stabilization, he experienced hepatic impairment on hospital day 37, with an alanine aminotransferase (ALT) level of 533 U/L and an aspartate aminotransferase (AST) level of 80 U/L. Glutathione and polyene phosphatidylcholine were added to protect his liver function, which returned to normal in 1 week. On hospital day 50, most lesions on his trunk became atrophic scars, and lesions on the extremities were either crusted or left with erosion from the crusts peeling off (**Fig. 5**). The patient was discharged with oral methylprednisolone 24 mg daily on hospital day 52. After discharge, methylprednisolone was gradually tapered off within 6 weeks. There were no new eruptions or any signs of relapse.

MATERIALS AND METHODS

Search strategy

To further investigate the characteristics of FUMHD in paediatric patients, a comprehensive literature search was conducted in 3 electronic databases: MEDLINE, PubMed and Web of Science. The search covered all available data from the inception of the databases to January 2023 (Appendix S1). A combination of medical subject headings (MeSH) and free-text terms related to FUMHD were used, such as "febrile ulceronecrotic Mucha-Habermann disease", "ulceronecrotic Mucha-Habermann disease" and "PLEVA fulminans" to create a search strategy finalized for PubMed. This was adjusted for use in other databases. Finally, the reference lists of all relevant articles were reviewed thoroughly to identify any additional potential cases.

Inclusion and exclusion criteria

Cases diagnosed with FUMHD in patients under the age of 18 years were included. Reviews, conference abstracts or posters were excluded. Duplicate cases in different reports were also

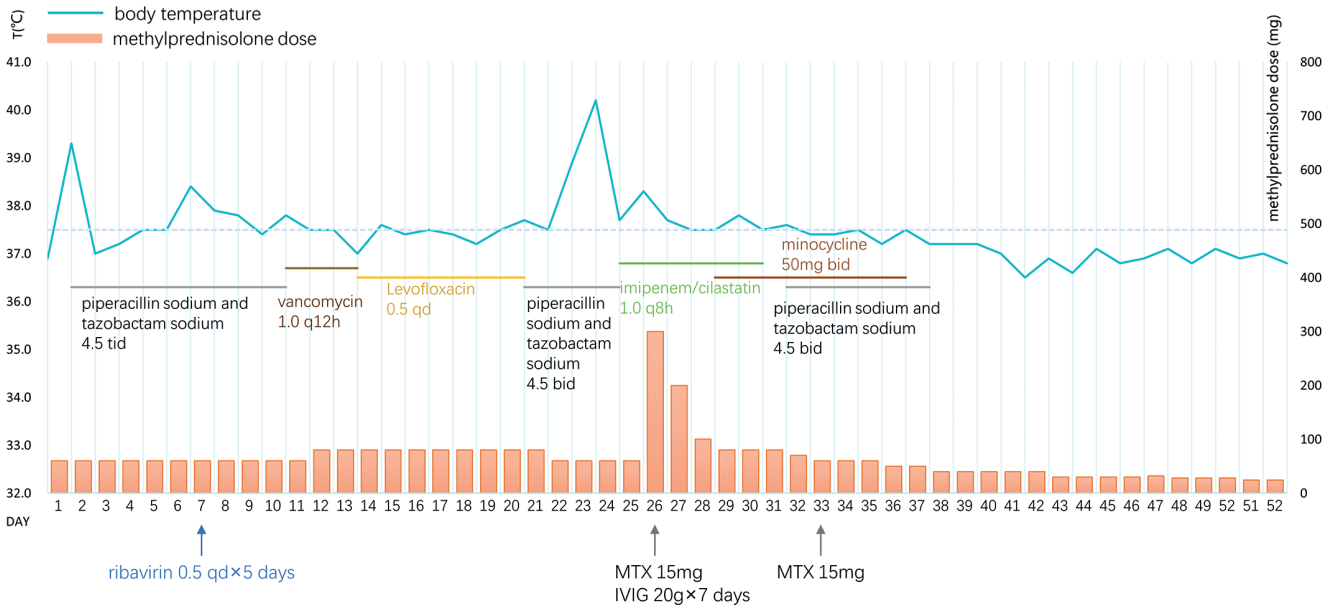

Fig. 4. Major treatments and body temperature. bid: twice daily; tid: three times daily; qd: once daily.

excluded. Cases not diagnosed with FUMHD or diagnosed with other diseases that looked like FUMHD, or cases that did not reach a distinctive diagnosis were excluded. Cases in which the patient's age was not precise were excluded. Only reports published in English language were included.

Fig. 5. On hospital day 50, most lesions on the patient's trunk were atrophic scars, and lesions on extremities were either crusted or left with erosion due to crusts peeling off.

Study selection and data extraction

The process of study selection and data extraction was conducted by 2 review authors (JL and JC).

Duplicate and irrelevant reports were initially screened out based on title and abstract. The full texts of the remaining studies were obtained and thoroughly evaluated by both authors for eligibility criteria. Independent data extraction was carried out by both reviewers, who used Excel to capture relevant information, including demographic information, such as age and sex, aetiology, bacterial culture results, mucosal lesion characteristics, immunohistochemistry and/or cytokines, systemic manifestations and/or laboratory finds, therapeutic interventions, and outcomes. Any discrepancies or disagreements in case selection or data extraction were discussed and resolved through consensus between the 2 reviewers. A flow diagram summarizing the selection process is shown in **Fig. 6**.

RESULTS

An initial search found 269 references, and an additional citation search identified another 8 records. After removing duplicated records as well as references that did not fulfil the inclusion criteria, 38 records were included for data retrieval. A total of 41 cases of FUMHD in paediatric patients were extracted from the included literature. The clinical features, therapies, and outcomes are summarized in **Table I** along with a case. Out of the 42 cases, 76.2% (32/42) were male patients, while 23.8% (10/42) were female. The distribution of cases by age group is depicted in **Fig. 7**. The majority of cases (88%) occurred among children 6 years or older. Five cases of FUMHD were reported in children under 3 years of age, an absence of documented cases in the age group spanning 3 to 5 years old. Two fatal cases were reported, both in male patients, one 9 years old and the other 10 years old.

DISCUSSION

In this study of 42 paediatric cases of FUMHD reported in the English language literature, including the current case, it was observed the that, although 5 cases of children under 3 years of age were diagnosed with FUMHD, 4 of these initially presented with a different admitting diagnosis, including Stevens-Johnson syndrome, Kawasaki disease and chickenpox infection. In the case detailed here, as in most cases of children above 6 years of age, the patients predominantly presented with generalized ulceronecrotic skin lesions with flexural accentuation, fever and sometimes mucous membrane and/or systemic involvement. In this age group, the clinical features were more typical and consistent with the diagnostic criteria proposed by Nofal et al. (5). Thus, the results showed that, in the paediatric population, FUMHD is most commonly seen in children over 6 years of age, with a more typical and consistent presentation. In contrast, in those younger than 6 years old, FUMHD is less common, and skin lesions are less typical. The exact aetiology and pathogenesis of FUMHD remain unestablished. However, a possible association with hypersensitivity to an infectious agent, particularly a virus, has been implicated in several reports. In the current review, 21.4% (9/42) of cases presented a potential causative aetiology, which included adenovirus, EBV, parvovirus, varicella zoster virus, measles vaccine, and mycoplasma. Whereas in adults, EBV, CMV (6), and HSV-2 (7) have been suspected as triggers for FUMHD.

Fig. 7. Number of febrile ulceronecrotic Mucha-Habermann disease cases reported, by age group.

Secondary infection was frequently observed in patients with FUMHD. In this review, 50% (21/42) of the paediatric FUMHD population reported positive skin and/or blood cultures, mainly with *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Escherichia coli*, *Acinetobacter baumannii*, *Candida*, etc. These organisms could exacerbate the condition and may lead to septicaemia and death (5). The underlying mechanism of how infectious agents could trigger or exacerbate FUMHD at the cellular and cytokine levels is not clear. An anecdotal study found that CMV exerts a direct effect on endothelial cells with subsequent dermal necrosis (6). Other studies have observed a predominant $CD8^+$ and/or $CD3^+$ T-cell infiltration in lesional skin, indicating a dysregulated T-cell response following a possible infection trigger (8). Tsianakas' study associated an increasingly dense perivascular lymphocytic infiltrate and high serum levels of tumour necrosis factor alpha (TNF-α) with the transition from PLEAVA to FUMHD (9). Wu et al. (10) revealed elevated interleukin (IL)-6, IL-8, IL-10, interferon-γ, and TNF-α levels in patients with FUMHD. T-cell clonality has also been implicated in the pathogenesis of FUMHD. It has been proposed that FUMHD with clonality represents a cutaneous T-cell lymphoma entity, and T-cell clonality may be related to disease severity (11). Monoclonal T cells were detected in several fatal cases in adults. However, to the best of our knowledge, only polyclonal T cells have been reported in children, and both fatal paediatric cases did not test T-cell clonality (12, 13). Thus, the prevalence and meaning of T-cell clonality in children with FUMHD require further investigation.

The patient described here presented with extensive mucosal involvement in the genital area. He also had liver dysfunction, lymphadenopathy and secondary infection. In the current literature review, mucous membrane involvement was found in 33.3% (14/42) of cases, and systemic manifestations and/or abnormal laboratory findings were observed in 76.2% (32/42) of cases. Systemic symptoms reported in the paediatric population include abdominal pain, diarrhoea, anaemia, liver dysfunction, lymphadenopathy, pulmonary involvement, arthritis, sepsis, disseminated intravascular coagulation, gastrointestinal (GI) haemorrhage and acute respiratory distress syndrome. Sepsis accounted for 21.4% (9/42) of cases in the paediatric population. Sepsis is considered an independent risk factor for poor prognosis (14). Both fatal cases reported in children were associated with pseudomonas septicaemia (12). In the current pa-

ActaDV Acta Dermato-Venereologica ActaDV Advances in dermatology and venereology

tient, high fever with elevated PCT and CRP raised the possibility of sepsis, even though blood culture results were negative. He also experienced an episode of liver dysfunction, which developed after initiation of MTX and a high-dose of corticosteroids highlighting the need to consider both systemic involvement and drug-induced liver impairment. Febrile dermatosis with denuded skin and possibly mucus membrane involvement should be considered in the differential diagnosis, such as Stevens-Johnson syndrome, Kawasaki disease, chickenpox infection, lymphoma, syphilis, vasculitis, and pyoderma gangrenosum.

In the current patient, despite initial treatment with systemic steroids, antibiotics and antiviral therapy, new lesions continued to develop and his overall condition also deteriorated, with high fever and severe pain at the ulceronecrotic sites. Therefore, a treatment regimen was implemented that included methylprednisolone pulse therapy, methotrexate and intravenous immunoglobulin. Within days, the patient became afebrile, new lesions development ceased, and old lesions began to heal. Although no consensus about first-line therapy for FUMHD has been reached as it is a rare condition, a wide variety of treatment modalities have been suggested to be effective, including systemic steroids, MTX, cyclosporine, dapsone, and IVIG. As treatment response differ among patients and patient usually treated with a combination therapy, it is difficult to reach a conclusion on a single treatment. However, as in the current case and other cases that failed initial systemic steroid therapy, MTX showed excellent results (15). Based on the finding of elevated cytokines in FUMHD, biologics have been applied in recent years. Wu et al. (10) successfully treated a FUMHD patient with tocilizumab, an IL-6 inhibitor, and ruxolitinib, a JAK 1/2 inhibitor, according to elevated cytokine levels, suggesting that the use of serum cytokine measurements may be beneficial in the targeted treatment of patients with FUMHD. Relapse was not observed in the current patient, although recurrences that are less severe than the primary episode and recurrent PLEVA have been reported in the literature (10).

In summary, we present here a typical FUMHD case in a 17-year-old boy and summarize the age distribution, superinfection rate, mucosal and systemic involvement, and treatment of paediatric FUMHD cases previously reported in the literature. This emphasizes the crucial role of early diagnosis, thorough evaluations, and appropriate treatment selection for these patients.
